INTRODUCTION

Living beings have a gift called regeneration. Humans have remarkable regenerative abilities. Workouts can be viewed as regulated bodily harm with post-training effects.

"Regeneration" is identical to the healing process for scratched skin.

Physical exertion, often known as physical stress, disrupts visceral organ balance (homeostasis). Red blood cells lose energy resources, including glycogen, enzymes, hormones, and oxygen. Physical injury includes micro-ruptures of muscle fibers, as well as inflammation of the muscles, tendons, and joints. This is the initial step in the training process to improve performance. The most effective approach is a combination of active regeneration and invasive recovery techniques. During the rest phase, the human body During rest, the human body adapts to new experiences and stressors.

Early training can promote glycogen repair, increased enzyme activity, and hormone redistribution.

Long-term effects include muscle mass growth, greater muscular innervation, blood vessel multiplication, and increased blood volume, including red cell multiplication. Some are blocked and expelled. Improved oxygen use and economy improve respiratory capacity, while cardiac hypertrophy increases cardiac capacity. Additionally, children experience bone growth stimulation and density increases.

Psychological adaptations include increased tolerance to pain and stress, as well as improved self-control and willpower. The body remembers.

The final burden against which it fought. The body not only adjusts and returns to its previous state, but also overloads to a greater level, known as supercompensation.

Individual recuperation procedures might range from

minutes to hours or days, as seen in the chart below.

Required recovery time for selected biological factors [1].

This knowledge begs a simple question: how long will it take to complete one supercompensation cycle? However, the answer is ambiguous. One thing is certain: the rehabilitation process always takes longer than Time for exercise. What is known precisely is the training time. When physical stress is focused in a short period of time, such as a sprint interval, recovery time is measured.

minutes. You can set as many repetitions as you can recover in the given time window. Sustained workouts can take a few hours and require a full day of recovery time. The supercompensation cycle includes daily or weekly training sessions, with regeneration lasting weeks or months. The training regiment typically involves multiple supercompensation cycles. The Secret of Correct Proper training requires adequate recuperation time between workouts. Based on the supercompensation graph, the optimal time to begin the following session is when performance reaches the top of the curve or slightly later.

Repeating the appropriate supercompensation cycle improves performance significantly. Starting successive sessions before supercompensation can lead to insufficient recovery.

Excessive effort can lead to tiredness, overreaching, and overtraining

Definition of Supercompensation Training The body strives for equilibrium, adapting to environmental stressors. Training involves manipulating the body's response to stress.

Adaptation to stress in order to maintain equilibrium. The adaption process is reasonably predictable. In training, the intended adaptive reaction is known as supercompensation. The supercompensation model remains the most straightforward depiction of the training process. The body is recovering from a state of extreme weariness.

The supercompensation effect includes physiological, psychological, and technical responses. The concept of a single supercompensation curve is incorrect as different physical attributes respond at varying speeds. Basically, each physical quality has Physical quality has its own unique supercompensation curve.

The timing of supercompensation varies depending on the duration of biological regeneration processes during recovery. For instance, replenishing creatine phosphate

The British Journal of Sports Medicine

takes a few seconds to a few minutes to return to normal levels, while lactic acid removal takes only a few minutes. However, glycogen-reloading (restoration) in the muscle, the main aerobic energy resource, can last up to 24 hours or even longer, extending the time of compensation and supercompensation. The synthesis of new enzymes (proteins) can take hours or days.

This adaptive phenomena is a continual, wave-like process. When all factors are properly adjusted and the work-to-recovery ratio is reached, the consequence is a continuous increase.

The sinusoidal curve pointed to higher-level performance. For effective supercompensation, the subject must be healthy. Training amount, intensity, and frequency must be tailored to each individual. Excessive training might hinder a person's ability to return to their baseline and prevent supercompensation. Overly easy training results in minimal adaptive responses. If exceedingly easy training is repeated across multiple cycles, the principle of reversibility applies. Proper training load and time are crucial for optimal results. According to the fitness fatigue theory [2], the fitness benefit of training is gradual and long-lasting, but the tiredness effect is shorter but more significant. Both of them Workouts have direct effects on fitness and weariness levels. Workouts can cause exhaustion in the short term, but can also lead to long-term adaptations in motor skills.

Supercompensation is a sports science idea that emphasizes increased glycogen levels in muscles, among other factors. It improves fitness by reducing weariness. Supercompensation occurs shortly after training, when the body is exhausted. Training during supercompensation is beneficial to the body compared to resuming training after recovery.

During recovery, the body aims to return to its previous energy level, therefore training will not significantly improve an individual's fitness level.

Waiting until the recuperation period ends and supercompensation begins allows individuals to set a higher standard for fitness or energy levels.

This ensures the subject gets the most out of the instruction in a shorter period of time.

Observing the evolution from initial fitness to supercompensation level, along with a healthy diet and training routine, can improve an athlete's general well-being and performance.

Compete in sporting competitions with increased endurance and strength.

Exercise fatigues the body; rest helps it to recover. Repeating this process allows the body to acclimate to different levels of exertion, leading to improved physical performance.

Supercompensation is essential for young people to develop, and for adults to maintain or slow down a decline in performance.
